HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

HANDLING CONVEXITY-LIKE CONSTRAINTS IN VARIATIONAL PROBLEMS*

QUENTIN MÉRIGOT[†] AND ÉDOUARD OUDET[‡]

Abstract. We provide a general framework to construct finite-dimensional approximations of the space of convex functions, which also applies to the space of c -convex functions and to the space of support functions of convex bodies. We give precise estimates of the distance between the approximation space and the admissible set. This framework applies to the approximation of convex functions by piecewise-linear functions on a mesh of the domain and by other finite-dimensional spaces such as tensor-product splines. We show how these discretizations are well suited for the numerical solution of problems of calculus of variations under convexity constraints. Our implementation relies on proximal algorithms and can be easily parallelized, thus making it applicable to large-scale problems in dimension two and three. We illustrate the versatility and the efficiency of our approach on the numerical solution of three problems in calculus of variation: three-dimensional denoising, the principal agent problem, and optimization within the class of convex bodies.

Key words. convexity, second-order constraints, convergence analysis, support function

1. Introduction. Several problems in the calculus of variations come with natural convexity constraints. In optimal transport, the Brenier theorem asserts that every optimal transport plan can be written as the gradient of a convex function, when the cost is the squared Euclidean distance. Jordan, Kinderlehrer, and Otto showed [10] that some evolutionary PDEs such as the Fokker–Planck equation can be reformulated as a gradient flow of a functional in the space of probability densities endowed with the natural distance constructed from optimal transport, namely, the Wasserstein space. In the corresponding time-discretized schemes, each timestep involves the solution of a convex optimization problem over the set of gradient of convex functions. In a different context, the principal agent problem proposed by Rochet and Choné [23] in economy also comes with natural convexity constraints. Despite the possible applications, the numerical implementation of these variational problems has been lagging behind, mainly because of a nondensity phenomenon discovered by Choné and Le Meur [6].

Choné and Le Meur discovered that some convex functions cannot be approximated by piecewise-linear convex functions on a regular grid (such as the grid displayed in Figure 1). More precisely, they proved that piecewise-linear convex functions on the regular grid automatically satisfy the inequality $\frac{\partial^2 f}{\partial x \partial y} \geq 0$ in the sense of distributions. Since there exist convex functions that do not satisfy this inequality, this implies that the union of the spaces of piecewise-linear convex functions on the regular grids $(G_\delta)_{\delta>0}$ is not dense in the space of convex functions on the unit square. More-

FIG. 1. Illustration of the nondensity result phenomena of Choné and Le Meur on the grid G_δ (top left). We consider the convex function $f(x, y) = \max(0, x + y - 1)$ on $[0, 1]^2$ and its projection g on the intersection $\mathcal{H}_{M_\varepsilon} \cap E_\delta$, where E_δ is the space of piecewise-linear functions on G_δ and $\mathcal{H}_{M_\varepsilon}$ is the space of function satisfying the relaxed convexity constraints of Definition 2.1. The error $|f - g|$ is displayed for three different choices of grid size, and $\varepsilon \ll \delta$. One can observe that the maximum error $\|f - g\|_\infty$ remains almost constant regardless of δ . (In all figures, the upper left and lower right corners corresponds to the value 0.2.)

over, this difficulty is local, and it is likely that for any fixed sequence of meshes, one can construct convex functions f that cannot be obtained as limits of piecewise-linear convex functions on these meshes. This phenomenon makes it challenging to use P^1 finite elements to approximate the solution of variational problems with convexity constraints.

1.1. Related works. In this section, we briefly discuss approaches that have been proposed in the last decade to tackle the problem discovered by Choné and Le Meur.

Mesh versus grid constraints. Carlier, Lachand-Robert, and Maury proposed in [5] to replace the space of P^1 convex functions by the space of the space of *convex interpolates*. For every fixed mesh, a piecewise-linear function is a convex interpolate if it is obtained by linearly interpolating the restriction of a convex function to the node of the mesh. Note that these functions are not necessarily convex, and the method is therefore not interior. Density results are straightforward in this context but the number of linear constraints which have to be imposed on node values is rather large. The authors observe that in the case of a regular grid, one needs $\simeq m^{1.8}$ constraints in order to describe the space of convex interpolates, where m stands for the number of nodes of the mesh.

Aguilera and Morin [1] proposed a finite-difference approximation of the space of convex functions using discrete convex Hessians. They prove that it is possible to impose convexity by requiring a linear number of nonlinear constraints with respect to the number of nodes. The leading fully nonlinear optimization problems are solved using semidefinite programming codes. Whereas convergence is proved in a rather general setting, the practical efficiency of this approach is limited by the capability of semidefinite solvers. In a similar spirit, Oberman [19] considers the space of functions that satisfy local convexity constraints on a finite set of directions. By changing the size of the stencil, the author proposed different discretizations which lead to exterior or interior approximations. Estimates of the quality of the approximation are given for smooth convex functions.

Higher-order approximation by convex tensor-product splines. An important number of publications have been dedicated in recent years to solving shape preserving least square problems. For instance, different sufficient conditions have been introduced to force the convexity of the approximating functions. Whereas this problem is well understood in dimension one, it is still an active field of research in the context of multivariate polynomials like Bézier or tensor-spline functions. We refer the reader to Jüttler [11] and references therein for a detailed description of recent results. In this article, Jüttler describes an interior discretization of convex tensor-product splines. This approach is based on the so called “Blossoming theory” which makes it possible to linearize constraints on the Hessian matrix by introducing additional variables. Based on this framework, the author illustrates the method by computing the L^2 projection of some given function into the space of convex tensor-product splines. Two major difficulties have to be pointed out. First, the density of convex tensor splines in the space of convex functions is absolutely nontrivial, and one may expect phenomena similar to those discovered by Choné and Le Meur. Second, the proposed algorithm leads to a very large number of linear constraints.

Dual approaches. Lachand-Robert and Oudet [13] developed a strategy related to the dual representation of a convex body by its support functions. They rely on a simple projection approach that amounts to the computation of a convex hull, thus avoiding the need to describe the constraints defining the set of support functions. To the best of our knowledge, this article is the first one to attack the question of solving problems of calculus of variations within convex bodies. The resulting algorithm can be interpreted as a nonsmooth projected gradient descent and gave interesting results on difficult problems such as Newton’s or Alexandrov’s problems. In a similar geometric framework, Oudet studied in [21] approximations of convex bodies based on Minkowski sums. It is well known in dimension two that every convex polygon can be decomposed as a finite sum of segments and triangles. While this result cannot be generalized to higher dimension, this approach still allows the generation of random convex polytopes. This process was used by the author to study numerically two problems of calculus of variations on the space of convex bodies with additional width constraints.

Ekeland and Moreno-Bromberg [7] proposed a dual approach for parameterizing the space of convex functions on a domain. Given a finite set of points S in the domain, they parameterize convex functions by their value f_s and their gradient v_s at those points. In order to ensure that these couples of values and gradients $(f_s, v_s)_{s \in S}$ are induced by a convex function, they add for every pair of points in S the constraints $f_t \geq f_s + \langle t - s, v_s \rangle$. This discretization is interior, and it is easy to show that the phenomenon of Choné and Le Meur does not occur for this type of approximation.

However, the high number of constraints makes it difficult to solve large-scale problems using this approach. Mirebeau [18] is currently investigating an adaptative version of this method that would allow its application to larger problems.

1.2. Contributions. We provide a general framework to construct approximations of the space of convex functions on a bounded domain that satisfies a Lipschitz bound. Our approximating space is a finite-dimensional polyhedron that is a subset of a finite-dimensional functional space that satisfies a finite number of linear constraints. The main theoretical contribution of this article is a bound on the (Hausdorff) distance between the approximating polyhedron and the admissible set of convex functions, which is summarized in Theorem 2.11. This bound implies in particular the density of the discretized space of functions in the space of convex functions. Our discretization is not specific to approximation by piecewise-linear functions on a triangulation of the domain and can easily be extended to approximations of convex functions within other finite-dimensional subspaces, such as the space of tensor-product splines. This is illustrated numerically in section 6.

This type of discretization is well suited to the numerical solution of problems of calculus of variations under convexity constraints. For instance, we show how to compute the L^2 projection onto the discretized space of convex functions in dimension $d = 2, 3$ by combining a proximal algorithm [2] and an efficient projection operator on the space of one-dimensional (1D) discrete convex functions. Because of the structure of the problem, these 1D projection steps can be performed in parallel, thus making our approach applicable to large-scale problems in higher dimension. We apply our nonsmooth approach to a denoising problem in dimension three in section 5. Other problems of calculus of variations under convexity constraints, such as the principal-agent problem, can be solved using variants of this algorithm. This aspect is illustrated in section 6.

Finally, we note in section 3 that the discretization of the space of convex functions we propose can be generalized to other spaces of functions satisfying similar constraints, such as the space of support functions of convex bodies. The proximal algorithm can also be applied to this modified case, thus providing the first method able to approximate the projection of a function on the sphere onto the space of support functions of convex bodies. Section 7 presents numerical computations of L^p projections (for $p = 1, 2, \infty$) of the support function of a unit regular simplex onto the set of support functions of convex bodies with constant width. We believe that these projection operators could be useful in the numerical study of a famous conjecture due to Bonnesen and Fenchel [4] concerning Meissner's convex bodies.

Notation. Given a metric space X , we denote $\mathcal{C}(X)$ the space of bounded continuous functions on X endowed with the norm of uniform convergence $\|\cdot\|_\infty$. Every subset L of the space of affine forms on $\mathcal{C}(X)$ defines a convex subset \mathcal{H}_L of the space of continuous functions by duality, denoted by

$$(1.1) \quad \mathcal{H}_L := \{g \in \mathcal{C}(K); \forall \ell \in L, \ell(g) \leq 0\}.$$

2. A relaxation framework for convexity. In this section, we concentrate on the relaxation of the standard convexity constraints for clarity of exposition. Most of the propositions presented below can be extended to the generalizations of convexity presented in section 3. Let X be a bounded convex domain of \mathbb{R}^d , and let \mathcal{H} be the

FIG. 2. (Left) The discretized convexity constraints are enforced on the discrete segments c_{pq} joining pairs of points of an ε -sampling of the boundary $U_\varepsilon \subseteq \partial X$. (Right) A triangulation of the domain X , which can be used to define a finite-dimensional subspace E_δ of continuous piecewise-linear functions on X . Note that ε must be greater than δ . The relation between the parameters δ and ε is studied in Theorems 2.4–2.11.

set of continuous convex functions on X . We define L_k as the set of linear forms ℓ on $\mathcal{C}(K)$ which can be written as

$$(2.1) \quad \ell(g) = g\left(\sum_{i=1}^k \lambda_i x_i\right) - \left(\sum_{i=1}^k \lambda_i g(x_i)\right),$$

where x_1, \dots, x_k are k distinct points chosen in X and where $(\lambda_i)_{1 \leq i \leq k}$ belongs to the $(k-1)$ -dimensional simplex Δ^{k-1} . In other words, $\lambda_1, \dots, \lambda_k$ are nonnegative numbers whose sum is equal to one. Since we are only considering continuous functions, \mathcal{H}_{L_k} and \mathcal{H} coincide as soon as $k \geq 2$.

We introduce in Definition 2.1 below a discretization M_ε of the set of convexity constraints L_2 . Choné and Le Meur proved in [6] that the union of the spaces of piecewise-linear convex functions on regular grids of the square is *not dense* in the space of convex functions on this domain. This means that we need to be very careful in order to apply the convexity constraints M_ε to finite-dimensional spaces of functions. If one considers the space E_δ of piecewise-linear functions on a triangulation of the domain with edgelengths bounded by δ , then $\mathcal{H}_{M_\varepsilon} \cap E_\delta = \mathcal{H} \cap E_\delta$ as soon as $\varepsilon \ll \delta$. In this case, one can fall in the pitfall identified by Choné and Le Meur, as illustrated in Figure 1. Our goal in this section is to show that it is possible to choose ε as a function of δ so that $\mathcal{H}_{M_\varepsilon} \cap E_\delta$ becomes dense in \mathcal{H} as δ goes to zero. Before stating our main theorem, we need to introduce some definitions.

DEFINITION 2.1 (discretized convexity constraints). *Given any triple of points (x, y, z) in X such that z belongs to $[x, y]$, we define a linear form ℓ_{xyz} by*

$$(2.2) \quad \ell_{xyz}(g) := g(z) - \frac{\|zy\|}{\|xy\|}g(x) - \frac{\|xz\|}{\|xy\|}g(y).$$

Here and below, we set $\|xy\| := \|x - y\|$ to emphasize the notion of distance between x and y . By convention, when we write ℓ_{xyz} , we implicitly assume that z lies on the segment $[x, y]$. Consider a subset $U_\varepsilon \subseteq \partial X$ such that for every point x in ∂X there exists a point x_ε in U_ε with $\|x - x_\varepsilon\| \leq \varepsilon$ (see Figure 2). Given any pair of distinct points (p, q) in U_ε , we let c_{pq} be the discrete segment defined by

$$c_{pq} := \left\{ p + \varepsilon i \frac{(q-p)}{\|q-p\|}; i \in \mathbb{N}, 0 \leq i \leq \|q-p\|/\varepsilon \right\}.$$

Finally, we define the following discretized set of constraints:

$$(2.3) \quad M_\varepsilon := \{\ell_{xyz}; \ x, y, z \in c_{pq} \text{ for some } p, q \in U_\varepsilon \text{ and } z \in [x, y]\}.$$

DEFINITION 2.2 (interpolation operator). A (linear) interpolation operator is a continuous linear map \mathcal{I}_δ from the space $\mathcal{C}(X)$ to a finite-dimensional linear subspace $E_\delta \subseteq \mathcal{C}(X)$, whose restriction to E_δ is the identity map. We assume that the space E_δ contains the affine functions on X and that the linear interpolation operator \mathcal{I}_δ satisfies these properties:

$$\begin{aligned} (L1) \quad & \text{Lip}(\mathcal{I}_\delta f) \leq C_I \text{Lip} f, \\ (L2) \quad & \|f - \mathcal{I}_\delta f\|_\infty \leq \delta \text{Lip}(f), \\ (L3) \quad & \|f - \mathcal{I}_\delta f\|_\infty \leq \frac{1}{2} \delta^2 \text{Lip}(\nabla f). \end{aligned}$$

In practice, we consider families of linear interpolation operators parameterized by δ , and we assume that $C_I \geq 1$ is constant for the whole family.

Example. Consider a triangulation of a polyhedral domain X such that each triangle has diameter at most δ . Define E_δ as the space of functions that are linear on the triangles of the mesh and $\mathcal{I}_\delta(f)$ as the linear interpolation of f on the mesh. Then $(E_\delta, \mathcal{I}_\delta)$ is an interpolation operator and satisfies (L1)–(L3). Other interpolation operators can be derived from higher-order finite elements, tensor-product splines, etc.

DEFINITION 2.3 (superior limit of sets). The superior limit of a sequence of subsets (A_n) of $\mathcal{C}(X)$ is defined by

$$\overline{\lim}_{n \rightarrow \infty} A_n := \{f \in \mathcal{C}(X); \exists f_n \in A_n, \text{ s.t. } \lim_{n \rightarrow \infty} f_n = f\}.$$

The following theorem shows that the nondensity phenomenon identified by Choné and Le Meur doesn't occur when ε is chosen large enough, as a function of δ . This theorem is a corollary of the more quantitative Theorem 2.11. The remainder of this section is devoted to the proof of Theorem 2.11.

THEOREM 2.4. Let X be a bounded convex domain X and $(\mathcal{I}_\delta)_{\delta > 0}$ be a family of linear interpolation operators. Let f be a function from \mathbb{R}_+ to \mathbb{R}_+ s.t.

$$\lim_{\delta \rightarrow 0} f(\delta) = 0, \quad \lim_{\delta \rightarrow 0} \delta / f(\delta)^2 = 0.$$

We let B_{Lip}^γ denote the set of γ -Lipschitz functions on X . Then,

$$(2.4) \quad \mathcal{H} \cap B_{\text{Lip}}^{\gamma/C_I} \subseteq \left[\overline{\lim}_{\delta \rightarrow 0} \mathcal{H}_{M_{f(\delta)}} \cap B_{\text{Lip}}^\gamma \right] \subseteq \mathcal{H} \cap B_{\text{Lip}}^\gamma.$$

2.1. Relaxation of convexity constraints. The first step needed to prove Theorem 2.4 is to show that every function that belongs to the space $\mathcal{H}_{M_\varepsilon}$ is close to a convex function on X for the norm $\|\cdot\|_\infty$. This result follows from an explicit upper bound on the distance between any function in $\mathcal{H}_{M_\varepsilon}$ and its convex envelope.

DEFINITION 2.5 (convex envelope). Given a function g on X , we define its convex envelope \bar{g} by the following formula:

$$(2.5) \quad \bar{g}(x) := \min \left\{ \sum_{i=1}^{d+1} \lambda_i g(x_i); \ x_i \in X, \lambda \in \Delta^d \text{ and } \sum_i \lambda_i x_i = x \right\},$$

where Δ^d denotes the d -simplex, i.e., $\lambda \in \mathbb{R}_+^{d+1}$ and $\sum \lambda_i = 1$. The function \bar{g} is convex, and by construction its graph lies below the graph of g .

PROPOSITION 2.6. For any function g in the space $\mathcal{H}_{M_\varepsilon}$, the distance between g and its convex envelope \bar{g} is bounded by $\|g - \bar{g}\|_\infty \leq \text{const}(d)\text{Lip}(g)\varepsilon$.

This proposition follows from a more general result concerning a certain type of relaxation of convexity constraints, which we call α -relaxation.

DEFINITION 2.7 (α -Relaxation). Let M, L be two sets of affine forms on the space $\mathcal{C}(X)$. The set M is called an α -relaxation of L , where α is a function from $\mathcal{C}(X)$ to $\mathbb{R}_+ \cup \{+\infty\}$, if the following inequality holds:

$$(2.6) \quad \forall \ell \in L, \forall g \in \mathcal{C}(K), \exists \ell_g \in M, |\ell(g) - \ell_g(g)| \leq \alpha(g).$$

PROPOSITION 2.8. Consider an α -relaxation M of L_2 . If g lies in \mathcal{H}_M , the distance between g and its convex envelope \bar{g} is bounded by $\|g - \bar{g}\|_\infty \leq d\alpha(g)$.

Proof. Let us show first that, assuming that g is in \mathcal{H}_M , the following inequality holds for any form ℓ in L_k :

$$(2.7) \quad \ell(g) \leq k\alpha(g).$$

For $k = 2$, this follows at once from our hypothesis. Indeed, there must exist a linear form ℓ_g in M that satisfies (2.6) so that $\ell(g) \leq \ell_g(g) + \alpha(g)$. Since g lies in \mathcal{H}_M , $\ell_g(g)$ is nonpositive and we obtain (2.7). The case $k > 2$ is proved by induction. Consider λ in the simplex Δ^{k-1} and points x_1, \dots, x_k in X . We assume $\lambda_1 < 1$ and we let $\mu_i = \lambda_i/(1 - \lambda_1)$ for any $i \geq 2$. The vector $\mu = (\mu_2, \dots, \mu_k)$ lies in Δ^{k-2} , and therefore $y = \sum_{i \geq 2} \mu_i x_i$ belongs to X . Applying the inductive hypothesis (2.7) twice, we obtain

$$\begin{aligned} g(\lambda_1 x_1 + (1 - \lambda_1)y) - (\lambda_1 g(x_1) + (1 - \lambda_1)g(y)) &\leq \alpha(g), \\ g(y) - \left(\sum_{i=2}^k \mu_i g(x_i) \right) &\leq (k-1)\alpha(g). \end{aligned}$$

The sum of the first inequality and $(1 - \lambda_1)$ times the second one gives (2.7). Now, consider the convex envelope \bar{g} of g . Given any family of points (x_i) and coefficients (λ_i) such that $\sum \lambda_i x_i = x$, we consider the form $\ell(f) := f(x) - \sum \lambda_i f(x_i)$. Applying (2.7) to ℓ gives

$$g(x) - d\alpha(g) \leq \sum \lambda_i g(x_i)$$

Taking the minimum over the (x_i) , (λ_i) such that $\sum \lambda_i x_i = x$, we obtain the desired inequality $|g(x) - \bar{g}(x)| \leq d\alpha(g)$. \square

In order to deduce Proposition 2.6 from Proposition 2.8, we should take $\alpha(g)$ proportional to $\text{Lip}(g)$. We use a technical lemma that gives an upper bound on the difference between two linear forms corresponding to convexity constraints in term of Lip .

LEMMA 2.9. Let x, y, z and x', y', z' be six points in X . Assume the following:

- (i) $\max(\|x - x'\|, \|y - y'\|, \|z - z'\|) \leq \eta$;
- (ii) $z \in [x, y]$, $z' \in [x', y']$.

Then, $|\ell_{xyz}(g) - \ell_{x'y'z'}(g)| \leq 6\eta\text{Lip}(g)$.

Proof. We define λ by the relation $z = \lambda x + (1 - \lambda)y$, and λ' is defined similarly. We also define $\ell_i(g) := g(z) - (\lambda'g(x) + (1 - \lambda')g(y))$. Then,

$$|\ell_{xyz}(g) - \ell_{x'y'z'}(g)| \leq |\ell_{x'y'z}(g) - \ell_i(g)| + |\ell_i(g) - \ell_{xyz}(g)|.$$

The first term is easily bounded by $2\eta\text{Lip}(g)$, while the second term is bounded by $|\lambda - \lambda'|\text{Lip}(g)\|xy\|$.

$$\begin{aligned} |\lambda - \lambda'| &= \left| \frac{\|zy\|}{\|xy\|} - \frac{\|z'y'\|}{\|x'y'\|} \right| \\ &\leq \left| \frac{\|zy\| - \|z'y'\|}{\|xy\|} \right| + \left| \frac{\|z'y'\|}{\|x'y'\|} \cdot \frac{\|x'y'\| - \|xy\|}{\|xy\|} \right| \leq 4\eta/\|xy\|. \end{aligned}$$

Overall, we get the desired upper bound. \square

Proof of Proposition 2.8. Our goal is to show that M_ε is an α -relaxation of L_2 . Consider three points x, y, z in X such that z lies inside the segment $[x, y]$. The straight line (x, y) intersects the boundary of X in two points a and b . By hypothesis, there exist two points p and q in U_ε such that the distances $\|a - p\|$ and $\|b - q\|$ are bounded by ε . The maximum distance between the segments $[a, b]$ and $[p, q]$ is then also bounded by ε and the maximum distance between the segment $[a, b]$ and the finite set c_{pq} by 2ε . This means that there exist three points $x_\varepsilon, y_\varepsilon$, and z_ε in c_{pq} such that $\max(\|x - x_\varepsilon\|, \|y - y_\varepsilon\|, \|z - z_\varepsilon\|) \leq 2\varepsilon$. Using Lemma 2.9, we deduce that $\|\ell_{xyz}(g) - \ell_{x_\varepsilon y_\varepsilon z_\varepsilon}(g)\| \leq \alpha(g) := 12\varepsilon\text{Lip}(g)$. This implies that M_ε is an α -relaxation of L_2 , and the statement follows from Proposition 2.8. \square

2.2. Hausdorff approximation. In this section, we use the estimation of the previous paragraph to prove a quantitative version of Theorem 2.4, using the notion of directed Hausdorff distance.

DEFINITION 2.10 (Hausdorff distances). *The directed or half-Hausdorff distance between two subsets A, B of a $\mathcal{C}(X)$ is denoted $\text{h}_H(A|B)$:*

$$(2.8) \quad \text{h}_H(A|B) = \min \{r \geq 0; \forall f \in A, \exists g \in B, \|f - g\|_\infty \leq r\}.$$

Note that this function is not symmetric in its argument.

THEOREM 2.11. *Let X be a bounded convex domain of \mathbb{R}^d and $I_\delta : \mathcal{C}(X) \rightarrow E_\delta$ be interpolation operator satisfying (L1)–(L3). We let B_{Lip}^γ be the set of γ -Lipschitz functions on X . Then, assuming $\gamma \geq 2C_I \text{diam}(X)$,*

$$(2.9) \quad \text{h}_H(B_{\text{Lip}}^\gamma \cap E_\delta \cap \mathcal{H}_{M_\varepsilon} | B_{\text{Lip}}^\gamma \cap \mathcal{H}) \leq \text{const}(d)\gamma\varepsilon,$$

$$(2.10) \quad \text{h}_H(B_{\text{Lip}}^{\gamma/C_I} \cap \mathcal{H} | B_{\text{Lip}}^\gamma \cap E_\delta \cap \mathcal{H}_{M_\varepsilon}) \leq \text{const} \frac{\gamma^2 \delta}{\varepsilon^2} \text{diam}(X).$$

Let $B_{\mathcal{C}^{1,1}}^\kappa$ be the set of functions with κ -Lipschitz gradients ($\kappa \geq 1$). Then,

$$(2.11) \quad \text{h}_H(B_{\mathcal{C}^{1,1}}^\kappa \cap \mathcal{H} | E_\delta \cap \mathcal{H}_{M_\varepsilon}) \leq \text{const} \cdot \kappa^2 \text{diam}(X)^2 \frac{\delta^2}{\varepsilon^2}.$$

Choice of the parameter ε . The previous theorem has implications on how to choose ε as a function of δ in order to obtain theoretical convergence results. In practice, the estimations given by the items (i) and (ii) below seem to be rather pessimistic, and in applications we always choose ε to be a small constant times δ .

- (i) If one chooses $\varepsilon = f(\delta)$, where f is a function from \mathbb{R}_+ to \mathbb{R}_+ such that $\lim_{\delta \rightarrow 0} f(\delta) = 0$ and $\lim_{\delta \rightarrow 0} \delta/f(\delta)^2 = 0$, the upper bounds in (2.9)–(2.10) converge to zero when δ does. This implies the convergence result stated in Theorem 2.4.

- (ii) We can choose ε so as to equate the two upper bound in (2.9)–(2.10), i.e., $\varepsilon \simeq \delta^{1/3}$. This suggests that the best rate of convergence in Hausdorff distance that one can expect from this analysis, in order to recover all convex functions $\mathcal{H} \cap B_{\text{Lip}}^\gamma$, is in $O(\delta^{1/3})$.
- (iii) On the other hand, (2.11) shows that convex and $\mathcal{C}^{1,1}$ functions are easier to approximate by discrete convex functions. In particular, if f is merely a superlinear function, i.e., $\lim_{\delta \rightarrow 0} f(\delta) = 0$ and $\lim_{\delta \rightarrow 0} \delta/f(\delta) = 0$, then, with $\varepsilon = f(\delta)$, the upper bounds of both (2.9) and (2.11) converge to zero.

The following easy lemma shows that the space $\mathcal{H}_{M_\varepsilon} \cap E_\delta$ has a nonempty interior for the topology induced by the finite-dimensional vector space E_δ as soon as $\delta < \varepsilon$. This very simple fact is the key to the proof of Theorem 2.11.

LEMMA 2.12. *Consider the function $s(x) := \|x - x_0\|^2$ on X , where x_0 is a point in X , and the interpolating function $s_\delta := \mathcal{I}_\delta s$. Then,*

$$\max_{\ell \in M_\varepsilon} \ell(s_\delta) \leq \delta^2 - \varepsilon^2.$$

Proof. Consider three points $x < z < y$ on the real line such that $|x - z| \geq \varepsilon$ and $|y - z| \geq \varepsilon$ and $z = \lambda x + (1 - \lambda)y$. Then,

$$\begin{aligned} z^2 - \lambda x^2 - (1 - \lambda)y^2 &= z^2 - \lambda(z + (x - z))^2 - (1 - \lambda)(z + (y - z))^2 \\ &= -[\lambda(x - z)^2 + (1 - \lambda)(y - z)^2] \leq -\varepsilon^2. \end{aligned}$$

Since the gradient of s is 2-Lipschitz, using (L3) we get $\|s - s_\delta\|_\infty \leq \delta^2$. Combining with the previous inequality, this implies $\ell(s_\delta) \leq \delta^2 - \varepsilon^2$ for every linear form ℓ in M_ε . \square

Proof of Theorem 2.11. Let g be a function in the intersection $\mathcal{H}_{M_\varepsilon} \cap B_{\text{Lip}}^\gamma$. Then, Proposition 2.8 implies that its convex envelope \bar{g} satisfies $\|g - \bar{g}\|_\infty \leq \text{const}(d)\text{Lip}(g)\varepsilon$. The Lipschitz constant of a function is not increased by taking its convex envelope, and thus \bar{g} belongs to $\mathcal{H} \cap B_{\text{Lip}}^\gamma$. This implies the upper bound given in (2.9).

On the other hand, given a convex function f in $\mathcal{H} \cap B_{\text{Lip}}^{\gamma/C_I}$, we consider the function $g := \mathcal{I}_\delta f$ defined by the interpolation operator. By property (L1) the function g belongs to B_{Lip}^γ , and by property (L2) one has for any linear form ℓ in L_2 ,

$$\begin{aligned} \ell(g) &= g(\lambda x + (1 - \lambda)y) - (\lambda g(x) + (1 - \lambda)g(y)) \\ &\leq f(\lambda x + (1 - \lambda)y) - (\lambda f(x) + (1 - \lambda)f(y)) + 2\delta\gamma \leq 2\delta\gamma. \end{aligned}$$

For $\eta < 1$, we let $g_\eta := (1 - \eta)g + \eta s_\delta$. Assuming $\delta \leq \varepsilon/2$, the previous inequality implies that for any linear form ℓ in M_ε ,

$$\ell(g_\eta) \leq (1 - \eta)2\delta\gamma + \eta(\delta^2 - \varepsilon^2) \leq 2\delta\gamma - \eta\varepsilon^2/2.$$

Consequently, assuming $4\delta\gamma \leq \eta\varepsilon^2$ the inequality $\ell(g_\eta) \leq 0$ holds for any linear form ℓ in M_ε , and g belongs to $\mathcal{H}_{M_\varepsilon}$. Moreover, using the fact that Lip is a seminorm, we have

$$\begin{aligned} \text{Lip}(g_\eta) &\leq (1 - \eta)\text{Lip}(g) + \eta\text{Lip}(s_\delta) \\ (2.12) \quad &\leq (1 - \eta)\gamma + 2C_I\eta \text{diam}(X). \end{aligned}$$

In the second inequality, we used property (L1) and $\text{Lip}(s) \leq 2 \text{diam}(X)$. By (2.12), the function g_η belongs to B_{Lip}^γ provided that $\gamma \geq 2C_I \text{diam}(X)$. From now on, we

fix $\eta = 4\delta\gamma/\varepsilon^2$ and let $h = g_\eta$, which by the discussion above belongs to $\mathcal{H}_{M_\varepsilon} \cap B_{\text{Lip}}^\gamma$. The distance between f and h is bounded by

$$\|f - h\|_\infty \leq \|f - g\|_\infty + \eta(\|g\|_\infty + \|s_\delta\|_\infty).$$

Since the space E_δ contains constant functions, we can assume that $\|g\|_\infty$ is bounded by $\text{Lip}(g) \text{diam}(X) \leq \gamma \text{diam}(X)$. Assuming $\varepsilon \leq \text{diam}(X)$,

$$\|f - h\|_\infty \leq \gamma\delta \left[1 + \frac{4}{\varepsilon^2} (\gamma \text{diam}(X) + \text{diam}(X)^2) \right] \leq 10 \frac{\gamma^2\delta}{\varepsilon^2} \text{diam}(X),$$

thus implying (2.10)

The proof of (2.11) is very similar. Given a convex function f in the intersection $\mathcal{H} \cap B_{\mathcal{C}_{1,1}}^\kappa$, we consider the function $g := \mathcal{I}_\delta f$ defined by the interpolation operator. Using (L3) one has for any linear form ℓ in L_2 ,

$$\begin{aligned} \ell(g) &= g(\lambda x + (1 - \lambda)y) - (\lambda g(x) + (1 - \lambda)g(y)) \\ &\leq f(\lambda x + (1 - \lambda)y) - (\lambda f(x) + (1 - \lambda)f(y)) + \delta^2\kappa \leq \delta^2\kappa. \end{aligned}$$

For $\eta < 1$, we set $g_\eta := (1 - \eta)g + \eta s_\delta$. Assuming $\delta \leq \varepsilon/2$, the previous inequality implies that for any linear form ℓ in M_ε ,

$$\ell(g_\eta) \leq (1 - \eta)\delta^2\kappa + \eta(\delta^2 - \varepsilon^2) \leq \delta^2\kappa - \eta\varepsilon^2/2.$$

Hence, the function $h := g_\eta$ belongs to $\mathcal{H}_{M_\varepsilon}$, where $\eta := 2\kappa\delta^2/\varepsilon^2$. Using the fact that E_δ contains an affine function, we can assume $g(x_0) = 0$, $\nabla g(x_0) = 0$ for some point x_0 in X , so that $\|g\|_\infty \leq \kappa \text{diam}(X)^2$. Combining this with property (L3), we get the following upper bound, which implies (2.11):

$$\begin{aligned} \|f - h\|_\infty &\leq \|f - g\|_\infty + \eta(\|g\|_\infty + \|s_\delta\|_\infty) \\ &\leq \text{const} \cdot \kappa\delta^2 \left[1 + \frac{\kappa \text{diam}(X)^2 + \text{diam}(X)^2}{\varepsilon^2} \right]. \quad \square \end{aligned}$$

3. Generalization to convexity-like constraints. In section 3.1 we show how to extend the relaxation of convexity constraints presented above to the constraints arising in the definition of the space of support function of convex bodies. We show in section 3.2 that both types of constraints fit in the general setting of c -convexity constraints, where c satisfies the so-called nonnegative cross-curvature condition.

3.1. Support functions. A classical theorem of convex geometry, stated as Theorem 1.7.1 in [24], for instance, asserts that any compact convex body in \mathbb{R}^d is uniquely determined by its *support function*. The support of a convex body K is defined by the following formula:

$$\underline{h}_K : x \in \mathbb{R}^d \mapsto \max_{p \in K} \langle x | p \rangle.$$

This function is positively 1-homogeneous and is therefore completely determined by its restriction \underline{h}_K on the unit sphere. We consider the space $\mathcal{H}^s \subseteq \mathcal{C}(\mathcal{S}^{d-1})$ of support functions of compact convex sets. This space coincides with the space of bounded functions on the sphere whose 1-homogeneous extensions to the whole space \mathbb{R}^d are convex.

LEMMA 3.1. *A bounded function g on the unit sphere is the support function of a bounded convex set if and only if for every x_1, \dots, x_k in the sphere, and every $(\lambda_1, \dots, \lambda_k) \in \Delta^{k-1}$,*

$$(3.1) \quad \|x\| g\left(\frac{x}{\|x\|}\right) \leq \sum_i \lambda_i g(x_i), \quad \text{where } x := \sum_i \lambda_i x_i.$$

Moreover, g is the support function of a convex set if it satisfies the inequalities for $k = 2$ only.

Following this lemma, we define L_k^s as the space of all linear forms that can be written as

$$(3.2) \quad \ell(g) := \left\| \sum_i \lambda_i x_i \right\| g\left(\frac{\sum_i \lambda_i x_i}{\|\sum_i \lambda_i x_i\|}\right) - \sum_i \lambda_i g(x_i),$$

where x_1, \dots, x_k are points on the sphere \mathcal{S}^{d-1} , and $(\lambda_1, \dots, \lambda_k)$ lies in Δ^{k-1} . With this notation at hand, we have another characterization of the space of support functions: \mathcal{H}^s coincides with the spaces $\mathcal{H}_{L_k^s}$ for any $k \geq 2$.

3.1.1. Discretization of the constraints. The discretization of the set L_2^s of constraints satisfied by support functions follows closely the discretization of the convexity constraints described earlier. Consider three points x , y , and z such that x and y are not antipodal and such that z belongs to the minimizing geodesic between x and y . We let z' be the radial projection of z on the extrinsic segment $[xy]$, i.e., such that $z'/\|z'\| = z$. Finally, we let $\lambda = \|zy\|/\|xy\|$ and define

$$\ell_{xyz}(g) := \|z'\| g(z) - \lambda g(x) - (1 - \lambda)g(y).$$

As before, we discard the constraint ℓ_{xyz} if z does not lie on the minimizing geodesic arc between x and y . Let U_ε be a subset of the sphere that satisfies the sampling condition

$$(3.3) \quad \forall u \in \mathcal{S}^{d-1}, \exists (\sigma, v) \in \{\pm 1\} \times U_\varepsilon \text{ s.t. } \|u - \sigma v\| \leq \varepsilon.$$

Then, for every vector u in U_ε we construct an ε -sampling c_u of the great circle orthogonal to u that is also $\frac{\varepsilon}{2}$ -sparse, i.e., $\|x - y\| \geq \frac{\varepsilon}{2}$ for any pair of distinct points x, y in c_u . The space of constraints we consider is the following:

$$M_\varepsilon^s = \{\ell_{xyz}; x, y, z \in c_u \text{ for some } u \in U_\varepsilon\}.$$

The proof of the following statement follows the proof of Proposition 2.6 and even turns out to be slightly simpler as one does not need to take care of the boundary of the domain.

PROPOSITION 3.2. *For any function h in the space $\mathcal{H}_{M_\varepsilon^s}$, there exists a bounded convex set K such that $\|h - h_K\|_\infty \leq \text{const}(d)\text{Lip}(g)\varepsilon$.*

It is possible to define a notion of interpolation operator on the sphere as in Definition 2.2 and to obtain Hausdorff approximation results similar to those presented in Theorem 2.4. The statement and proofs of the theorem being very similar, we do not repeat them. However, we show that the indicator function of the unit ball, i.e., the constant function equal to one, belongs to the interior of the set $\mathcal{H}_{M_\varepsilon^s}$. This is the analogue of Lemma 2.12, which was the crucial point of the proof of convergence for the usual convexity.

LEMMA 3.3. With $s(x) := 1$, one has $\max_{\ell \in M_\varepsilon^s} \ell(s) \leq -\text{const} \cdot \varepsilon^2$.

Proof. For every ℓ in M_ε^s , there exist three (distinct) points x, y, z in c_u for some u in U_ε . Let z' denote the radial projection of z on the segment $[x, y]$. Then, $\ell_{xyz}(s) = \|z'\| - 1$. By construction, $\|x - z\|$ and $\|y - z\|$ are at least $\varepsilon/2$, and therefore $\|z'\| \leq 1 - \text{const} \cdot \varepsilon^2$, thus proving the lemma. \square

3.1.2. Support function as c -convex functions. Olikar [20] and Bertrand [3] introduced another characterization of support functions of convex sets, inspired by optimal transportation theory. They show that the logarithm of support functions coincides with c -convex functions on the sphere for the cost function $c(x, y) = -\log(\max(\langle x|y \rangle, 0))$. (See section 3.2 for a definition of c -convexity.)

LEMMA 3.4. The 1-homogeneous extension of a bounded positive function h on \mathcal{S}^{d-1} is convex if and only if the function $\varphi := \log(h)$ can be written as

$$\varphi(x) = \sup_{y \in \mathcal{S}^{d-1}} -\psi(y) - c(x, y),$$

where $c(x, y) = -\log(\max(\langle x|y \rangle, 0))$ and $\psi : \mathcal{S}^{d-1} \rightarrow \mathbb{R}$.

Proof. We show only the direct implication; the reverse implication can be found in [3]. By assumption $h = h_K$, where K is a bounded convex set that contains the origin in its interior, and let ρ_K be the radial function of K , i.e., $\rho_K(y) := \max\{r; ry \in K\}$. Then,

$$h_K(x) = \max_{p \in K} \langle x|p \rangle = \max_{y \in \mathcal{S}^{d-1}} \rho_K(y) \langle x|y \rangle.$$

Since $h_K > 0$, the maximum in the right-hand side is attained for a point y such that $\langle x|y \rangle > 0$. Taking the logarithm of this expression, we get

$$\varphi(x) = \max_{y \in \mathcal{S}^{d-1}} \log(\rho_K(y)) - c(x, y),$$

thus concluding the proof of the direct implication. \square

3.2. c -convex functions. In this paragraph, we show how the discretizations of the spaces of convex and support functions presented above can be extended to c -convex functions. This extension is motivated by a generalization of the principal-agent problem proposed by Figalli, Kim, and McCann [8]. Thanks to the similarity between the standard convexity constraints and those arising in their setting, one could hope to perform numerical computations using the same type of discretization as those presented in section 2.

The authors of [8] prove that the set of c -convex functions is convex if and only if c satisfies the so-called nonnegative cross-curvature condition. Under the same assumption, we identify the linear inequalities that define this convex set of functions. Note that the numerical implementation of this section is left for future work.

Given a cost function $c : X \times Y \rightarrow \mathbb{R}$, where X and Y are two open and bounded subsets of \mathbb{R}^d , the c -transform and c^* -transform of lower semicontinuous functions $\varphi : X \rightarrow \mathbb{R}$ and $\psi : Y \rightarrow \mathbb{R}$ are defined by

$$\begin{aligned} \varphi^{c^*}(y) &:= \sup_{x \in X} -c(x, y) - \varphi(x), \\ \psi^c(x) &:= \sup_{y \in Y} -c(x, y) - \psi(y). \end{aligned}$$

A function is called c -convex if it is the c^* -transform of a lower semicontinuous function $\psi : Y \rightarrow \mathbb{R}$. The space of c -convex functions on X is denoted \mathcal{H}_c . We will need the following usual assumptions on the cost function c :

- (A0) $c \in \mathcal{C}^4(\overline{X} \times \overline{Y})$, where $X, Y \subseteq \mathbb{R}^n$ are bounded open domains.
 (A1) For every point y_0 in Y and x_0 in X , the maps

$$\begin{aligned} x \in \overline{X} &\mapsto -\nabla_y c(x, y_0), \\ y \in \overline{Y} &\mapsto -\nabla_x c(x_0, y) \end{aligned}$$

are diffeomorphisms onto their range (bi-twist).

- (A2) For every point y_0 in Y and x_0 in X , the sets $X_{y_0} := -\nabla_y c(X, y_0)$ and $Y_{x_0} := -\nabla_x c(x_0, Y)$ are convex (bi-convexity).

These conditions allow one to define the c -exponential map. Given a point y_0 in the space Y , the c -exponential map $\exp_{y_0}^c : X_{y_0} \rightarrow X$ is defined as the inverse of the map $-\nabla_y c(\cdot, y_0)$, i.e., it is the unique solution of

$$(3.4) \quad \exp_{y_0}^c(-\nabla_y c(x, y_0)) = x.$$

The following formulation of the nonnegative cross-curvature condition is slightly non-standard, but it agrees with the usual formulation for smooth costs under conditions (A0)–(A2), thanks to Lemma 4.3 in [8].

- (A3) For every pair of points (y_0, y) in Y the following map is convex:

$$(3.5) \quad v \in X_{y_0} \mapsto c(\exp_{y_0}^c v, y_0) - c(\exp_{y_0}^c v, y).$$

The main theorem of [8] gives a necessary and sufficient condition for the space \mathcal{H}_c of c -convex functions to be convex.

THEOREM 3.5. *Assuming (A0)–(A2), the space of c -convex functions \mathcal{H}_c is itself convex if and only if c satisfies (A3).*

The proof that (A0)–(A3) implies the convexity of \mathcal{H}_c given in [8] is direct but nonconstructive, as the authors show that the average of two functions φ_0 and φ_1 in \mathcal{H}_c also belongs to \mathcal{H}_c . The following proposition provides a set of linear inequality constraints that are both necessary and sufficient for a function to be c -convex.

PROPOSITION 3.6. *Assuming the cost function satisfies (A0)–(A3), a function $\varphi : X \rightarrow \mathbb{R}$ is c -convex if and only if it satisfies the following constraints:*

- (i) *for every y in Y , the map $\varphi_y : v \in X_y \mapsto \varphi(\exp_y^c v) + c(\exp_y^c v, y)$ is convex.*
- (ii) *for every x in X , the subdifferential $\partial\varphi(x)$ is included in Y_x .*

Note that the first set of constraints (i) can be discretized in an analogous way to the previous sections. On the other hand, the second constraint concerns the subdifferential of φ in the sense of semiconvex functions. It is not obvious how to handle this constraint numerically, except in the trivial case where Y_x coincides with the whole space \mathbb{R}^d for any x in X .

Proof. Suppose first that φ is c -convex. Then, there exists a function ψ such that $\varphi(x) = \psi^{c*}$ and one has

$$\varphi_y(v) = \sup_z [-\psi(z) - c(\exp_y^c v, z)] + c(\exp_y^c v, y).$$

Equation (3.5) implies that φ_y is convex as a maximum of convex functions.

Conversely, suppose that a map $\varphi : X \rightarrow \mathbb{R}$ is such that the maps φ_y are convex for any point y in Y , and let us show that φ is c -convex. Using the definition of φ_y , and the definition of the c -exponential (3.4), one has

$$\varphi(x) = \varphi_y(-\nabla_y c(x, y)) - c(x, y)$$

for any pair of points (x, y) in $X \times Y$. This formula and the convexity of φ_y imply in particular that the map φ is semiconvex. Consequently, for every point x in X , the subdifferential $\partial\varphi(x)$ is nonempty, and there must exist a point y in Y such that $v := -\nabla_x c(x, y)$ belongs to $\partial\varphi(x)$. Hence, x is a critical point of the map $\varphi - c(\cdot, y)$, and therefore v is a critical point of φ_y . By convexity, v is also a global minimum of φ_y , i.e., for every w in \overline{X}_y ,

$$\varphi(\exp_y^c w) + c(\exp_y^c w, y) \geq \varphi(x) + c(x, y).$$

Letting $x' = \exp_y^c w$, we get $\varphi(x') \geq \varphi(x) + c(x, y) - c(x', y)$. The function $\varphi(x) + c(x, y) - c(\cdot, y)$ is thus supporting φ at x . Since φ admits such a supporting function at every point x in X , it is a c -convex function. \square

4. Numerical implementation. In this section, we give some details on how to apply the relaxed convexity constraints presented in section 2 to the numerical solution of problems of calculus of variation with (usual) convexity constraints. Our goal is to minimize a convex functional \mathcal{F} over the set of convex functions \mathcal{H} . Our algorithm assumes that \mathcal{F} is easily proximable (see Definition 4.1). For any convex set K , we denote i_K the convex indicator function of K , i.e., the function that vanishes on K , and take value $+\infty$ outside of K . The constrained minimization problem can then be reformulated as

$$(4.1) \quad \min_{g \in \mathcal{C}(X)} \mathcal{F}(g) + i_{\mathcal{H}}(g).$$

The method that we present in this paragraph can be applied with minor modifications to support functions. Its extension to the other types of convexity constraints presented in section 3 will be the object of future work.

4.1. Discrete formulation. We are given a finite-dimensional subspace E of $\mathcal{C}(X)$ and a linear parameterization $\mathcal{P} : \mathbb{R}^N \rightarrow E$ of this space. This subspace E and its parameterization play a similar role to the interpolation operator in the theoretical section. For instance, we can let E be the space of piecewise-linear functions on a triangulation of X and let \mathcal{P} be the parameterization of this space by the values of the function at the vertices of the triangulation. For every point x in X , this parametrization induces a linear evaluation map $\mathcal{P}_x : \mathbb{R}^N \rightarrow \mathbb{R}$, defined by $\mathcal{P}_x \xi := (\mathcal{P}\xi)(x)$. By convention, if x does not lie in X , then $\mathcal{P}_x \xi = +\infty$. The convexity constraints in (4.1) are discretized using Definition 2.1:

$$(4.2) \quad \min_{\xi \in \mathbb{R}^N} \mathcal{F}(\mathcal{P}\xi) + i_{\mathcal{H}_{M_\varepsilon}}(\mathcal{P}\xi).$$

We now show how to rewrite the indicator function of the discretized convexity constraints $\mathcal{H}_{M_\varepsilon}$ as a sum of indicator functions. This allows us to exploit this particular structure to deduce an efficient algorithm.

Let $U_\varepsilon \subseteq \partial X$ be a finite subset such that every point of ∂X is at a distance at most ε from a point of U_ε . Given a pair of points $p \neq q$ in U_ε , we consider the discrete segment $c_{pq} := \{p + \varepsilon i(q - p) / \|q - p\| ; i \in \mathbb{N}, 0 \leq i \leq \|q - p\| / \varepsilon\}$. These geometric constructions are illustrated in Figure 2. The evaluation of a function $\mathcal{P}\xi$ on a discrete segment c_{pq} is a vector indexed by \mathbb{N} , which takes finite values only for indices in $\{0, \dots, |c_{pq}| - 1\}$:

$$\mathcal{P}_{pq}\xi = \left(\mathcal{P}\xi \left(p + \varepsilon i \frac{(q - p)}{\|q - p\|} \right) \right)_{i \in \mathbb{N}}.$$

Define \mathcal{H}_1 as the cone of vectors $(f_i)_{i \in \mathbb{N}}$ that satisfy the discrete convexity conditions $f_i \leq \frac{1}{2}(f_{i-1} + f_{i+1})$ for $i \geq 1$. The relaxed problem (4.2) is then equivalent to the following minimization problem:

$$(4.3) \quad \min_{\xi \in \mathbb{R}^N} \mathcal{F}(\mathcal{P}\xi) + \sum_{\substack{(p,q) \in U_\varepsilon^2 \\ p \neq q}} i_{\mathcal{H}_1}(\mathcal{P}_{pq}\xi).$$

Remark (number of constraints). In numerical applications, we set $\varepsilon = c\delta$, where c is a small constant, usually in the range $(1, 3]$. For a fixed convex domain X of \mathbb{R}^2 , there are $O(1/\varepsilon)$ constraints per discrete segment and $O(1/\varepsilon^2)$ such discrete segments. The total number of constraints is therefore $C := O(1/\varepsilon^3) = O(1/\delta^3)$. Moreover, a triangulation of X with maximum edglength δ has at least $N = O(1/\delta^2)$ points. This implies that the dependence of the number of constraints as a function of the number of points is given by $C = O(N^{3/2})$. This is slightly lower than the exponent $O(N^{1.8})$ found in [5]. Moreover, as shown below, the structure of the constraints in (4.3) is favorable for optimization.

4.2. Proximal methods. When the functional \mathcal{F} is linear, (4.3) is a standard linear programming problem. Similarly, when \mathcal{F} is quadratic and convex, this problem is a quadratic programming problem with linear constraints. Below, we show how to exploit the 1D structure of the constraints so as to propose an efficient and easy-to-implement algorithm based on a proximal algorithm. This algorithm allows us to perform the optimization when \mathcal{F} is a more general function. The version of the algorithm that we describe below is able to handle functions that are *easily proximal* (see Definition 4.1). Note that it would also be possible to handle functions \mathcal{F} whose gradient is Lipschitz using the generalized forward-backward splitting algorithm of [22].

DEFINITION 4.1 (proximal operator). *The proximal operator associated to a convex function $f : \mathbb{R}^N \rightarrow \mathbb{R}$ is defined as follows:*

$$(4.4) \quad \text{prox}_\gamma f(y) = \arg \min_{x \in \mathbb{R}^N} f(x) + \frac{1}{\gamma} \|x - y\|^2.$$

The function is called easily proximal if there exists an efficient algorithm able to compute its proximal operator. For instance, when f is the indicator function i_K of a convex set, $\text{prox}_\gamma f$ coincides with the projection operator on K , regardless of the value of γ .

The simultaneous-direction method of multipliers (SDMM) algorithm is designed to solve convex optimization problems of the following type:

$$\min_{x \in \mathbb{R}^N} g_1(L_1 x) + \dots g_m(L_m x),$$

where the $(L_i)_{1 \leq i \leq m}$ are matrices of dimensions $N_1 \times N, \dots, N_m \times N$ and the function $(g_i)_{1 \leq i \leq m}$ are convex and easily proximal. Moreover, it assumes that the matrix $Q := \sum_{i=1}^m L_i^T L_i$ is invertible, where L_i^T stands for the transpose of the matrix L_i . A summary of the SDMM algorithm is given in Algorithm 1. More details and variants of this algorithm can be found in [2]. Note that when applied to (4.3), every iteration of the outer loop of the SDMM algorithm involves the computation of several projection on the cone of 1D discrete functions \mathcal{H}_1 . These projections can be computed independently, thus allowing an easy parallelization of the optimization.

ALGORITHM 1. SDMM.

Input $\gamma > 0$ **Initialization** $(y_{1,0}, z_{1,0}) \in \mathbb{R}^{2N_1}, \dots, (y_{m,0}, z_{m,0}) \in \mathbb{R}^{2N_m}$ **For** $n = 0, 1, \dots$

$$x_n = Q^{-1} \sum_{i=1}^m L_i^T (y_{i,n} - z_{i,n})$$

For $i = 1, \dots, m$

$$s_{i,n} = L_i x_n$$

$$y_{i,n+1} = \text{prox}_\gamma g_i(s_{i,n} + z_{i,n})$$

$$z_{i,n+1} = z_{i,n} + s_{i,n} - y_{i,n+1}$$

4.3. Hinge algorithm. In the algorithm above, we need to compute the ℓ^2 projection of a vector (f_i) on the cone of discrete 1D convex functions \mathcal{H}_1 . In practice, (f_i) is supported on a finite set $\{0, \dots, n\}$, and one needs to compute the ℓ^2 projection of this vector onto the convex cone

$$\mathcal{H}_1^n = \{g : \{0, \dots, n\} \rightarrow \mathbb{R}; \forall i \in \{1, \dots, n-1\}, 2g_i \leq g_{i-1} + g_{i+1}\}.$$

This problem is classical, and several efficient algorithms have been proposed to solve it. Since the number of conic constraints is lower than the dimension of the ambient space $(n+1)$, the number of extreme rays of the polyhedral cone \mathcal{H}_1^n is bounded by n . In this case the extreme rays coincide with the edges of the cone. Moreover, as noted by Meyer [17], these extreme rays can be computed explicitly. This remark allows one to parameterize the cone \mathcal{H}_1^n by the space $\mathbb{R} \times \mathbb{R}_+^n$, thus recasting the projection onto \mathcal{H}_1^n into a much simpler nonnegative least squares problem. To solve this problem, we use the simple and efficient exact active set algorithm proposed by Meyer [17]. In our implementation, we reuse the active set from one proximal computation to the next one. This improves the computation time by up to an order of magnitude.

5. Application I: Denoising. Our first numerical application focuses on the L^2 projection onto the set of convex functions on a convex domain. We illustrate the efficiency of our relaxed approach in the context of denoising. Let u^* be a convex function on a domain X in \mathbb{R}^d . We approximate this function by a piecewise-linear function on a mesh, and the values of the function at the node of the mesh are additively perturbed by Gaussian noise: $u_0(p) = u^*(p) + c\mathcal{N}(0, 1)$, where $\mathcal{N}(0, 1)$ stands for the standard normal distribution and c is a small constant. Our goal is then to solve the following projection problem in order to estimate the original function u^* :

$$\min_{u \in \mathcal{H}} \|u - u_0\|_{L^2(X)}.$$

As described in previous sections, our discretization of the space of convex functions is not interior. However, thanks to Theorem 2.11, we obtain a converging discretization process that uses fewer constraints than previously proposed interior approaches. More explicitly, we illustrate below our method on the following three-dimensional denoising setting. Let $u_0(x, y, z) = \frac{x^2}{3} + \frac{y^2}{4} + \frac{z^2}{8}$, $X = [-1, 1]^3$ and set $c = \frac{1}{40}$. We carried our computation on a regular grid made of 80^3 points and we look for an approximation in the space of piecewise-linear functions. The parameter used to discretize the convexity constraints is set to $\varepsilon = 0.02$. Figure 3 displays the result of the SDMM algorithm after 10^4 iterations. This computation took less than 5 minutes on a standard computer.

FIG. 3. *Denoising a convex graph by 1D projections.*FIG. 4. *Denoising the support function of a convex body. Left: the perturbed support function of the icosaedron. Right: its projection into the set of support functions.*

To illustrate the versatility of the method, we performed the same denoising experience in the context of support functions, using the discretization explained in section 3. As in the previous example, we consider a support function perturbed by additive Gaussian noise $h_0(p) = h^*(p) + c\mathcal{N}(0, 1)$. In the numerical application, h^* is the support function of the unit isocaedron and $c = 0.05$, as shown on the left of Figure 4. Our goal is to compute the projection of h_0 to the space of support functions:

$$\min_{h \in \mathcal{H}^s} \|h - h_0\|_{L^2(\mathcal{S}^{d-1})}^2.$$

In order to relax the constraint \mathcal{H}^s , we imposed 1D constraints on a family of 2000 great circles of \mathcal{S}^{d-1} uniformly distributed and a step discretization of every circular arc equal to 0.02. We obtained a very satisfactory reconstruction of h_i after 10^4 iterations of the SDMM algorithm, as displayed on the right of Figure 4.

6. Application II: Principal-agent problem. The principal-agent problem formalizes how a monopolist selling products can determine a set of prices for its products so as to maximize its revenue, given a distribution of customer—the agents. We describe the simplest geometric version of this problem in the next paragraph.

Various instances of this problem are then used as numerical benchmarks for our relaxed convexity constraints.

6.1. Geometric principal agent problem. Let X be a bounded convex domain of \mathbb{R}^d , a distribution of agent $\rho : X \rightarrow \mathbb{R}$, and a finite subset $K \subseteq X$. The *monopolist* or *principal* needs to determine a *price menu* π for pickup or deliveries, so as to maximize its revenue. The principal has to take into account the two following constraints: (i) the agents will try to maximize their utility and (ii) there is a finite subset $K \subseteq X$ of facilities that compete with the principal and force him to set its price $\pi(y)$ to zero at any y in K . For a given price menu π , the utility of a location y for an agent located at a position x in X is given by $u_\pi(x, y) = -\frac{1}{2}\|x - y\|^2 - \pi(y)$. The fact that each agent tries to maximize his utility means that he will choose a location that balances closeness and price. The maximum utility for an agent x is given by

$$u_\pi(x) := \max_{y \in X} u(x, y) = -\frac{1}{2}\|x\|^2 + \max_{y \in X} \left[\langle x|y \rangle - \frac{1}{2}\|y\|^2 - \pi(y) \right].$$

Let us denote $\bar{u}_\pi(x)$ the convex function $u_\pi(x) + \frac{1}{2}\|x\|^2$. This function is differentiable for almost every point x in X , and at such a point the gradient $\nabla \bar{u}_\pi(x)$ agrees with the best location for x , i.e., $\nabla \bar{u}_\pi(x) = \arg \max_y u(x, y)$. This implies the following equality:

$$\bar{u}_\pi(x) = \langle x|\nabla \bar{u}_\pi(x) \rangle - \frac{1}{2}\|\nabla \bar{u}_\pi(x)\|^2 - \pi(\nabla \bar{u}_\pi(x)).$$

Our final assumption is that the cost of a location for the principal is constant. Our previous discussion implied that the total revenue of the principal, given a price menu π , is computed by the following formula:

$$\begin{aligned} R(\pi) &= \int_X \pi(\nabla \bar{u}_\pi(x)) \rho(x) dx \\ (6.1) \quad &= - \int_X \left[\bar{u}_\pi(x) - \langle x|\nabla \bar{u}_\pi(x) \rangle + \frac{1}{2}\|\nabla \bar{u}_\pi(x)\|^2 \right] \rho(x) dx. \end{aligned}$$

Changing the unknown from π to $v := \bar{u}_\pi$, the assumption that the price vanishes on the set K translates as $u_\pi \geq \max_{y \in K} -\frac{1}{2}\|\cdot - y\|^2$ or equivalently

$$v(x) = \bar{u}_\pi(x) \geq \max_{y \in K} \langle x|y \rangle - \frac{1}{2}\|y\|^2.$$

Thus, we reformulate the principal's problem in term of v as the minimization of the following functional:

$$(6.2) \quad L(v) := \int_X \left[v(x) + \frac{1}{2}\|\nabla v(x) - x\|^2 \right] \rho(x) dx,$$

where the maximum is taken over the set of convex functions $v : X \rightarrow \mathbb{R}$ that satisfy the lower bound $v \geq \max_{y \in K} \langle \cdot|y \rangle - \frac{1}{2}\|y\|^2$.

6.2. Numerical results. We present three numerical experiments. The first one concerns a linear variant of the principal-agent problem. The second and third concern the geometric principal-agent problem presented above: we maximize the functional L of (6.2) over the space of nonnegative convex functions, with $X = B(0, 1)$ and $X = [1, 2]^2$, respectively, ρ constant, and $K = \{(0, 0)\}$.

TABLE 1
Convergence of numerical approximations for the linear principal-agent.

# points	ε	$ M - M_{\text{opt}} $	$\ u - u_{\text{opt}}\ _{\infty}$	CPU
900	0.06	$8 \cdot 10^{-5}$	$1.15 \cdot 10^{-2}$	11s
3600	0.03	$8 \cdot 10^{-5}$	$1.00 \cdot 10^{-2}$	28s
8100	0.02	$4.3 \cdot 10^{-5}$	$8.46 \cdot 10^{-3}$	87s

TABLE 2
Convergence of numerical approximations for the geometric principal-agent problem (radial case).

# points	ε	$ L - L_{\text{opt}} $	$\ u - u_{\text{opt}}\ _{\infty}$	CPU
30×30	0.06	$1.3 \cdot 10^{-3}$	$2 \cdot 10^{-3}$	11s
60×60	0.03	$9.8 \cdot 10^{-4}$	$1.6 \cdot 10^{-3}$	251s
90×90	0.02	$9.7 \cdot 10^{-4}$	$1.1 \cdot 10^{-3}$	500s

6.2.1. Linear principal agent. As a first benchmark, we consider a variant of the principal-agent problem where the minimized functional is linear in the utility function u [15]. The goal is to minimize the functional

$$M(u) := \int_X (u(x) - \langle \nabla u | x \rangle) \rho(x) dx,$$

where $X = [0, 1]^2$ and $\rho = 1$, over the set of convex functions whose gradient is included in $[0, 1]^2$. The solution to this problem is known explicitly:

$$u_{\text{opt}}(x_1, x_2) = \max\{0, x_1 - a, x_2 - a, x_1 + x_2 - b\},$$

where $a = 2/3$ and $b = (4 - \sqrt{2})/3$. We solve the linear principal-agent problem on a regular grid meshing $[0, 1]^2$ and compare it to the exact solution on the grid points. Table 1 displays the numerical results for various grid sizes and choices of ε .

6.2.2. Geometric principal agent, radial case. In order to evaluate the accuracy of our algorithm, we first solve the (nonlinear) geometric principal-agent problem on the unit disk with $K = \{(0, 0)\}$ and ρ constant. The optimal profile is radial in this setting, and one can obtain a very accurate description of the optimal radial component by solving a standard convex quadratic programming problem. In parallel, we compute an approximation of the two-dimensional solution on an unstructured mesh of the disk. On the left of Figure 5, we show that our solution matches the line of the 1D profile after 10^3 iterations of the SDMM algorithm for $\delta = 0.12$ and $\varepsilon = 1/50$. Table 2 shows the speed of convergence of our method, in terms of both computation time and accuracy, with 10^3 iterations.

6.2.3. Geometric principal agent, Rochet–Choné case. We recover numerically the so-called bunching phenomena predicted by Rochet and Choné [23] when $X = [1, 2]^2$, ρ is constant, and $K = \{(0, 0)\}$, thus confirming numerical results from [7, 18, 1]. On the right of Figure 5, we show the numerical solution defined on a regular mesh of the square of size 60×60 with $\varepsilon = 0.02$. In this computation, the interpolation operator is constructed using P3 finite elements, so as to illustrate the flexibility of our method.

7. Application III: Closest convex set with constant width. A convex compact set K of \mathbb{R}^d has constant width $\alpha > 0$ if all its projections on every straight

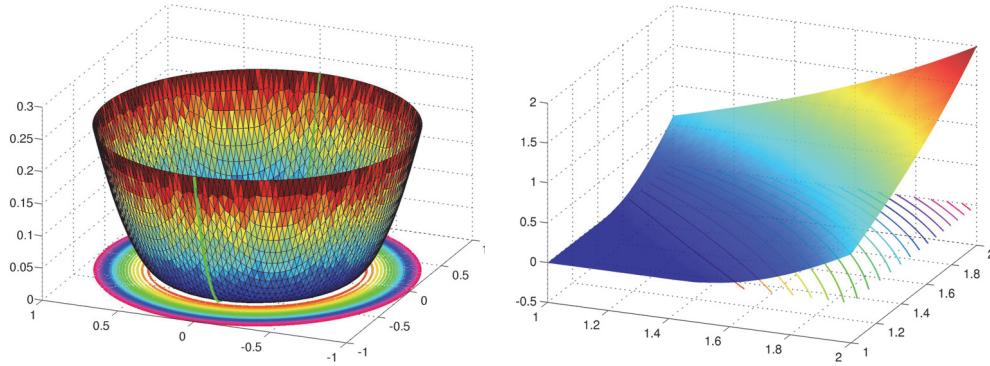

FIG. 5. (Left) Numerical approximation to the principal-agent problem on $X = B(0, 1)$ with $\delta = 1/60$ and $\varepsilon = 1/50$. The profile of the 1D solution is reported as a bold line on the graph. (Right) Numerical approximation to the principal-agent problem with $X = [1, 2]^2$ by P3 finite elements.

line are segments of length α . This property is equivalent to the following constraints on the support function of K :

$$(7.1) \quad \forall \nu \in \mathcal{S}^{d-1}, \quad h_K(\nu) + h_K(-\nu) = \alpha.$$

Surprisingly, balls are not the only bodies having this property. In dimension two, for instance, Reuleaux's triangles, which are obtained by intersecting three disks of radius α centered at the vertices of an equilateral triangle, have constant width α . Moreover, Reuleaux's triangles have been proved by Lebesgue and Blaschke to minimize the area among two-dimensional bodies with prescribed constant width.

In dimension three, this problem is more difficult. Indeed the mere existence of nontrivial three-dimensional bodies of constant width is not so easy to establish. In particular, no finite intersection of balls has constant width, except balls themselves [14]. As a consequence and in contrast to the two-dimensional case, the intersection of four balls centered at the vertices of a regular simplex is not of constant width. In 1912, Meissner described in [16] a process to turn this spherical body into an asymmetric bodies with constant width by smoothing three of its circular edges. This famous body is called the "Meissner tetrahedron" in the literature [12]. It is suspected to minimize the volume among three-dimensional bodies with the same constant width. Let us point out that Meissner construction is not canonical in the sense that it requires the choice of the set of three edges that have to be smoothed. As a consequence, there actually exist two kinds of Meissner tetrahedron having the same measure.

In these two constructions, the regular simplex seems to play a crucial role in the optimality. (See also [9] for a more rigorous justification of this intuition.) It is therefore natural to search for the body with constant width that is the closest to a regular simplex. In a Hilbert space, the projection on a convex set is uniquely defined. Thus, the Meissner tetrahedra cannot be obtained as projections of a regular simplex to the convex set $\mathcal{H}^s \cap \mathcal{W}$ with respect to the L^2 norm between support functions. Such an obstruction does not hold for the L^1 and L^∞ norms, which are not strictly convex. We illustrate below that our relaxed approach can be used to

TABLE 3
Numerical results for the projections of h_S .

	Surface	Volume	Width	Relative width error
L^1 projection of h_S	2.6616	0.36432	0.951	≈ 0.001
L^2 projection of h_S	2.5191	0.34312	0.920	≈ 0.003
L^∞ projection of h_S	2.1351	0.28081	0.835	≈ 0.001

FIG. 6. *Reconstruction of the convex bodies associated to the L^1 , L^2 , and L^∞ projection of h_S without prescribing the width value.*

numerically investigate these questions. The optimization problem that we have to approximate is

$$\min_{h \in \mathcal{H}^s \cap \mathcal{W}} \|h_0 - h\|_{L^p(\mathcal{S}^2)}, \quad 1 \leq p \leq \infty,$$

where \mathcal{W} is the set of functions of \mathcal{S}^2 which satisfy the width constraints (7.1).

As explained in section 3, we relax the constraint of being a support function by imposing convexity-like conditions on a finite family of great circles of the sphere. In the experiments presented below the number of vertices in our mesh of \mathcal{S}^2 is 5000. We choose a family of 2000 great circles of \mathcal{S}^2 uniformly distributed (with respect to their normal direction) and a step discretization of every circular arc equal to 0.02. Finally, the constant width constraint \mathcal{W} is approximated by imposing that antipodal values of the mesh must satisfy a set of linear equality constraints, which can be easily implemented in the proximal framework depicted in section 4.2. Note that in this first experience, the value of the width constraint is not imposed.

We present in Table 3 and Figure 6 our numerical description of the projections of the support function of a regular simplex in the set of support functions of constant width bodies for the L^1 , L^2 , and L^∞ norms. One can observe that the resulting support functions describe a body with constant width within an error of magnitude 0.1%. In other words the gap between the minimal width and the diameter is relatively less than 0.001. In the L^1 case we obtain a convex body whose surface area and volume are close to those of a Meissner body of the same width, within a relative error of less than 0.01. We also performed the same experiment starting from the support functions of others platonic solids. For any of these other solids, and when the value of the width is not imposed, the closest body with constant seems to always be a ball.

Acknowledgments. The first author would like to thank Robert McCann for introducing him to the principal-agent problem and Young-Heon Kim for interesting discussions. The authors would like to acknowledge the support of the French Agence

Nationale de la Recherche under ANR-11-BS01-014-01 (TOMMI) and ANR-12-BS01-0007 (Optiform).
